Abstract

We look at chaotic systems evolving in fractal phase space. The entropy change in time due to the fractal geometry is assimilated to the information growth through the scale refinement. Due to the incompleteness, at any scale, of the information calculation in fractal support, the incomplete normalization $\sum_i p_i^q = 1$ is applied throughout the paper. It is shown that the information growth is nonadditive and is proportional to the trace-form $\sum_i p_i - \sum_i p_i^q$ so that it can be connected to several nonadditive entropies. This information growth can be extremized to give, for non-equilibrium systems, power law distributions of evolving stationary state which may be called “maximum entropic evolution”.

1 Introduction

The aim of this paper is to study the information evolution of special systems whose phase space volumes are or map into fractals or multifractals (e.g., dissipative chaotic systems whose phase space volume maps into fractal attractors for long time $t \rightarrow \infty$).

One of the motivations of this work is related to the generalizations[1] of Boltzmann and Gibbs entropies which are, in general, connected to dense

phase space (Γ -space). Some of these generalized entropies, e.g., Havrda-Charvat-Tsallis one[2, 3] or Rényi one[4], are believed to have some connections with fractal geometry and chaotic behavior of non-equilibrium systems at stationary states. Our idea in this work is to look at the geometry of the fractal phase space, to calculate the information from simple geometrical consideration, and to see what is the property of the evolution of this information and if it has something to do with the generalized entropies.

We suppose an ensemble moving in a fractal phase space, the volume of its initial condition gradually mapping into fractal structure. That is, as its trajectories run over all the permitted phase points, its phase volume is covered more and more such that a scale refinement would be necessary to calculate the occupied volume more and more exactly. Consequently, the long time behavior of the system of interest is likened to its ensemble behavior : the information evolution in time is estimated by the information growth during the scale refinement. This is a crucial point of this work. Due to the incompleteness of the counting of state points or of the calculation of geometrical elements of fractal structure at any given scale[5], the discussion will be made on the basis of the so called incomplete normalization of probability proposed for the study of the complex systems having physical states accessible to the systems but inaccessible to theoretical treatments[5, 6, 7, 8].

2 Fractal phase space normalization

To take into account the incompleteness of countable information for a fractal phase space of dimension d_f embedded in a Euclidean space of dimension d , we have put[5] :

$$\sum_{i_k=1}^{v_k} p_{i_k}^q = 1, \quad (1)$$

where v_k is only the number of the accessible states at the k^{th} iteration, q is given by $q = d_f/d$, and $p_{i_k} = s_{i_k}/S_0$ with s_{i_k} the volume of the i_k^{th} element of the fractal at the k^{th} iteration[5, 8] and S_0 the volume of the phase space containing the fractal.

The normalization in Eq.(1) for incomplete probability distribution was for the first time discussed by Tribus[9] some decades ago in the context of probability theory applied to decision theory in engineering and economics where p_i^q was one of the solutions to the functional equation for logic induction

and might be considered as an effective probability. The probability defined in Eq.(1) is different from the usual frequency or time definition which is normalized. Here the probability p_i 's do not sum to one because it is the ratio of a non-differentiable fractal structure to an integrable and differentiable homogeneous space. This definition is analogous to that proposed in [10] to define probability p_i by the ratio of the number of trajectories (volume s_i) on the element s_i to the total number of trajectories (total volume S_0) of the initial conditions.

Eq.(1) has been called incomplete normalization. Its incompleteness means that the sum over all the v_k elements at the k^{th} iteration does not mean the sum over all the states of the system under consideration, because the volume $s_k(i)$ does not represent the real number of states or trajectories on the element which, as expected for any fractal structure, evolves with k . So at any given order k , the summation over all possible elements is not equal to the complete summation over all possible states.

3 Information growth due to fractal

So there is expansion or contraction of state volume when we refine the phase space scale. This evolution of the accessible phase volume of a system during the scale refinement should be interpreted as follows : the extra state points

$$\Delta_{i_k} = \sum_{j_{k+1}=1}^{n_{i_k}} s_{j_{k+1}} - s_{i_k} \quad (2)$$

acquired from certain element i_k at the iterate of $(k+1)^{th}$ order are just the number of unaccessible states at k^{th} order with respect to $(k+1)^{th}$ order, where n_{i_k} is the number of elements $s_{j_{k+1}}$ replacing, at $(k+1)^{th}$ iterate, the element s_{i_k} . $\Delta_{i_k} > 0$ (or < 0) means that we have counted less (or more) states at k^{th} order than the states really accessible to the system. Δ_{i_k} contains the *accessible information gain* (AIG) through the $(k+1)^{th}$ iterate.

To illustrate the relation between this “hidden information” and the parameter q , let us suppose that *the probability density ρ is scale-invariant* with $\int_{S_0} \rho^q ds = 1$ according to incomplete normalization. At the iterate of order k , the information content on $s_k(i)$ is given by

$$I_k(i) = \int_{s_{i_k}} I(\rho) ds \quad (3)$$

where $I(\rho)$ is the information density. At $k + 1$ order, we have

$$I_{k+1}(i) = \int_{\sum_{j_{k+1}=1}^{n_{i_k}} s_{j_{k+1}}} I(\rho) ds. \quad (4)$$

Now we suppose constant ρ over each element i_k , i.e., $p_{i_k} \propto s_{i_k}$. This is true for very small elements after a long evolution of the system of interest or for the case where every phase point is visited with equal probability. Then AIG reads

$$\Delta I_k(i) = I_{k+1}(i) - I_k(i) = \int_{\Delta_{i_k}} I(\rho) ds = I(\rho) \Delta_{i_k} \quad (5)$$

The relative AIG is given by

$$\begin{aligned} R_{k \rightarrow (k+1)}(i_k) &= \Delta I_k(i) / I_k(i) \\ &= \sum_{j_{k+1}=1}^{n_{i_k}} \frac{p_{j_{k+1}}}{p_{i_k}} - 1. \end{aligned} \quad (6)$$

Eq.(6) suggests that the average value or the expectation of the relative AIG over all the fractal may be calculated with two possible methods.

1. By unnormalized expectation :

$$\begin{aligned} \bar{R}_{k \rightarrow (k+1)} &= \sum_{i_k=1}^{v_k} p_{i_k} R_{k \rightarrow (k+1)}(i_k) \\ &= \sum_{i_{k+1}=1}^{v_{k+1}} p_{i_{k+1}} - \sum_{i_k=1}^{v_k} p_{i_k} \end{aligned} \quad (7)$$

where v_k (or v_{k+1}) is the total number of elements of the fractal at k^{th} (or $(k + 1)^{th}$) iteration.

2. Or by normalized expectation with escort probability :

$$\begin{aligned} \tilde{R}_{k \rightarrow (k+1)} &= \frac{\sum_{i_k=1}^{v_k} p_{i_k} R_{k \rightarrow (k+1)}(i_k)}{\sum_{i_k=1}^{v_k} p_{i_k}} \\ &= \frac{\sum_{i_{k+1}=1}^{v_{k+1}} p_{i_{k+1}}}{\sum_{i_k=1}^{v_k} p_{i_k}} - 1. \end{aligned} \quad (8)$$

The total AIG from 0^{th} up to k^{th} iteration is then given by

$$R_k = \bar{R}_{0 \rightarrow k} = \tilde{R}_{0 \rightarrow k} = \sum_{i_k=1}^{v_k} p_{i_k} - 1 = \sum_{i_k=1}^{v_k} (p_{i_k} - p_{i_k}^q) \quad (9)$$

because $\sum_{i_0=1}^{v_0} p_{i_0} = S_0/S_0 = 1$.

So from just geometrical consideration, we end with an information change which is proportional to the trace-form $\sum_{i_k=1}^{v_k} (p_{i_k} - p_{i_k}^q)$. We see that if $q = 1$ or $d = d_f$, the fractal structure does not exist any more, and $R_k = 0$. So this is indeed an information evolution due to the fractal geometry of the phase space.

If one want to write $\wp_i = p_i^q$, then R_k reads $R_k = \sum_{i_k=1}^{v_k} \wp_{i_k}^{1/q} - 1$ with $\sum_{i_k=1}^{v_k} \wp_{i_k} = 1$. $\wp_{i_k}$ can be seen as a complete probability distribution. In this case, do not forget that $\wp_{i_k}$ is not the real probability p_{i_k} .

If we divide certain functional of R_k by the dimension difference $d_f - d$, we can get several of the trace form entropies in the long list[1] posited, from mathematical considerations, as possible alternatives to Gibbs or Shannon entropy $S = -\sum_i p_i \ln p_i$. For example, $\frac{R_k}{d_f - d}$ gives the Havrda-Charvat-Tsallis entropy $S_q = \frac{\sum_i p_i - \sum_i p_i^q}{q-1}$ [2, 3], $\frac{\ln(R_k+1)}{d_f - d}$ gives Rényi entropy $S^R = \frac{\ln \sum_i \wp_i^\alpha}{1-\alpha}$ ($\alpha = 1/q$) for complete distribution[4] or $S^R = \frac{\ln \sum_i p_i}{q-1}$ for incomplete distribution[11], and $\frac{(R_k+1)^{d_f/d} - 1}{d_f - d}$ gives Arimoto entropy $S^A = \frac{(\sum_i \wp_i^{1/q})^{q-1} - 1}{q-1}$ [12], among others. It is worth noticing that all these entropies recover Gibbs-Shannon entropy S when $q \rightarrow 1$ or $d_f \rightarrow d$.

4 Some properties of R_k

1. Nonadditivity : for a fractal of dimension d_f composed of two sub-fractals 1 and 2 of dimension d_{f_1} and d_{f_2} satisfying product joint probability $p_{i_{k_1} i_{k_2}} = p_{i_{k_1}} p_{i_{k_2}}$, it is easy to show the following nonadditivity :

$$R_{k_1 k_2}(1+2) = R_{k_1}(1) + R_{k_2}(2) + R_{k_1}(1)R_{k_2}(2). \quad (10)$$

2. Concavity and convexity : R_k is positive and concave for $q > 1$ and negative and convex for $q < 1$, as shown in Figure 1.

3. For a self-similar fractal whose n_{i_k} is the same for all elements and for any iteration order, the AIG per iteration given by Eq.(6) is independent of i_k :

$$R = \sum_{j_{k+1}=1}^n \frac{p_{j_{k+1}}}{p_{i_k}} - 1 = \sum_{j_{k+1}=1}^n r_j - 1, \quad (11)$$

where r_j is the scale factors of the j^{th} element of the n ones for an iteration. If all r_j 's are equal : $r_j = 1/m^d$, we get

$$R = n/m^d - 1 = (1 - q) \ln_q(1/m^d) \quad (12)$$

where $\ln_q$ is called generalized logarithm and given by $\ln_q x = \frac{x^{1-q}-1}{1-q}$.

For a Cantor set, $n = 2$, $m = 3$, $d = 1$ et $q = d_f = 0.63$, $R = -1/3$.

For a two scale Cantor set with, say, $r_1 = 1/5$ and $r_2 = 3/5$, q or d_f is determined by $(1/5)^q + (3/5)^q = 1$, $R = -1/5$.

For von Koch curve, $n = 4$, $m = 3$, $d = 1$, $q = d_f = 1.26$, and $R = 1/3$.

For Sierpinski gasket, $n = 3$, $m = 2$, and $d = 2$, so $d_f = \frac{\ln n}{\ln m} = 1.58$, $q = d_f/d = 0.79$ and $R = -0.25$.

For Menger's sponge, $n = 20$, $m = 3$, and $d = 3$, so $d_f = 2.73$, $q = d_f/d = 0.9$ and $R = -0.26$.

5 Some possible applications

Now we address stationary probability distribution of non-equilibrium non-additive systems. The actual idea of the nonextensive statistical mechanics (NSM) based on Havrda-Charvat-Tsallis entropy[3] is to maximize entropy, just for equilibrium state, to get the stationary power law distributions. This philosophy seems plausible for the systems that have much smaller relaxation time to reach stationary state than the necessary time interval for the interaction to change the state. But the method is not justified for stationary state in general or for non-equilibrium systems which are in evolution with their entropy changing constantly.

In view of the concavity ($q > 1$, $R_k > 0$) or convexity ($q < 1$, $R_k < 0$) of R_k (see Figure 1) and of its connections with different entropies or information measures, it can be easily checked that the maximum entropy principle

Figure 1: The concavity and convexity of the relative information growth R_k for $q > 0$ with a two probability distribution $p_1 = x$ and $p_2 = (1 - x)^{1/q}$ satisfying $\sum_{i=1}^2 p_i^q = 1$. R_k is concave for $q > 1$ and convex for $q < 1$.

is mathematically equivalent to the extremization of the information growth R_k . Our idea here is to extremize R_k in order to obtain the probability distributions of the stationary states. In this case, the stationary state is a kind of “dynamical equilibrium” or, more precisely, “equilibrium (stable) evolution” that, extremizes the information (entropy) growth R_k and maximizes the entropies at any moment with respect to other possible evolutions. For this reason, the probability distributions obtained from extremizing R_k can be called *probability distribution for maximum entropic evolution*. Following are some examples of power law distributions obtained by the R_k -extremum.

1. **The continued fraction map**[13] is given by $x_{n+1} = 1/x_n - \lfloor 1/x_n \rfloor$ where $\lfloor 1/x_n \rfloor$ is the integer part of $1/x_n$ and x_n is a real number between 0 and 1. The probability distribution is given by $\rho(x) = 1/(1+x) \ln 2$

and satisfies $\int_0^1 \rho(x)dx = 1$. This distribution can be obtained by extremizing

$$R_k = \int_0^1 \tilde{\rho}(x)dx - 1 \quad (13)$$

under the constraints associated with the normalization $\int_0^1 \tilde{\rho}^q(x)dx = 1$ and with the unnormalized expectation $\overline{x} = \int_{[0 < x < 1]} \tilde{\rho}(x)x dx$ or with the normalized expectation $\tilde{x} = \frac{\int_{[0 < x < 1]} \tilde{\rho}(x)x dx}{\int_{[0 < x < 1]} \tilde{\rho}(x)dx}$, we can obtain the distribution

$$\rho(x) = \tilde{\rho}^q(x) = \frac{c}{(1 - \beta x)^{q/(1-q)}} \quad (14)$$

where $q = 1/2$, $\beta = -1$ is the Lagrange multiplier associated with $\overline{x}$ and the constant $c = 1/\ln 2$ is determined by the normalization.

2. **The Ulam maps** is a logistic map $x_{n+1} = 1 - \mu x_n^2$ ($-1 < x < 1$) with $\mu = 2$. Its probability distribution is given by $\rho(x) = \frac{1}{\pi(1-x^2)^{1/2}}$ which is normalized[13]. By extremizing R_k under the constraints associated with $\int_{-1}^1 \tilde{\rho}(x)^q dx = 1$ and with the unnormalized expectation $\overline{x^2} = \int_{-1}^1 \tilde{\rho}(x)x^2 dx$ or with the normalized expectation $\widetilde{x^2} = \frac{\int_{-1}^1 \tilde{\rho}(x)x^2 dx}{\int_{-1}^1 \tilde{\rho}(x)dx}$, we can obtain a distribution

$$\rho(x) = \tilde{\rho}^q(x) = \frac{c}{(1 - \beta x^2)^{q/(1-q)}} \quad (15)$$

where $q = 1/3$, $\beta = 1$ is the Lagrange multiplier associated with $\overline{x^2}$ and the constant $c = 1/\pi$ is determined by the normalization.

3. **The Zipf-Mandelbrot's law** $\rho(x) = \frac{A}{(1-Bx)^\gamma}$ is an useful chaotic distribution for some complex systems[14], where A , B and γ are constants. Using the same machinery as above, one obtain :

$$\rho(x) = \frac{A}{(1 - \beta x)^{q/(1-q)}} \quad (16)$$

where $\beta = B$ is the Lagrange multiplier associated with $\overline{x}$, $1/q = 1+1/\gamma$ and A should be determined by the condition $\int_{-1}^1 \rho(x)dx = 1$.

6 Conclusion

In summing, we have discussed the accessible information growth (AIG) during long time evolution of some chaotic systems or through the scale refinement in their fractal phase space. AIG turns out to take the trace form $\sum_i p_i - \sum_i p_i^q$ so that it can be connected with several entropies which generalize the Gibbs-Shannon one. It is argued that, for non-equilibrium systems, it would be more natural to extremize AIG, instead of maximizing entropy, to get the stationary probability distributions. It turns out that this extremization is mathematically equivalent to the maximization of the relevant generalized entropies. Several power law distributions have been obtained from the extremization of AIG.

On the other hand, the AIG of this work has been calculated for chaotic systems whose phase space is or maps into fractals. So it may be invalid for other non-equilibrium systems that do not have this property. What is the information growth in that case? How to obtain the probability distribution for these non-equilibrium systems? Does the method of extremum information growth applies in general to them? What is the thermodynamics of the “dynamical equilibrium” of this nonadditive systems in constant evolution? All these questions, together with other fundamental questions about NSM, still remain open.
